Vector-Valued Image Regularization with PDEs: A Common Framework for Different Applications

David Tschumperlé and Rachid Deriche

Abstract—In this paper, we focus on techniques for vector-valued image regularization, based on variational methods and PDEs. Starting from the study of PDE-based formalisms previously proposed in the literature for the regularization of scalar and vector-valued data, we propose a unifying expression that gathers the majority of these previous frameworks into a single generic anisotropic diffusion equation. On one hand, the resulting expression provides a simple interpretation of the regularization process in terms of local filtering with spatially adaptive Gaussian kernels. On the other hand, it naturally disassembles any regularization scheme into the smoothing process itself and the underlying geometry that drives the smoothing. Thus, we can easily specialize our generic expression into different regularization PDEs that fulfill desired smoothing behaviors, depending on the considered application: image restoration, inpainting, magnification, flow visualization, etc. Specific numerical schemes are also proposed, allowing us to implement our regularization framework with accuracy by taking the local filtering properties of the proposed equations into account. Finally, we illustrate the wide range of applications handled by our selected anisotropic diffusion equations with application results on color images.

Index Terms—Diffusion PDEs, color image regularization, denoising, inpainting, vector-valued smoothing, anisotropic filtering, flow visualization.

1 INTRODUCTION AND STATE OF THE ART

For several years, regularization algorithms have raised a huge interest in the computer vision and image processing community. It basically consists of simplifying a signal or an image, in a way that only interesting features are preserved while unimportant data (considered as “noise”) are removed. By the way, such methods have direct applications for image denoising, but their abilities to create simplified representations of data are very interesting as well, when dealing with features extraction (edges and corners in images for instance). Actually, it is often one of the key stage performed by high-level algorithms in computer vision or image processing areas, such as object recognition, tracking, etc. Regularization algorithms are used as low-level steps in more complex processing pipelines and their adequations to the considered problems are crucial. For these reasons, a lot of regularization frameworks have already been proposed in the literature. Pioneering works in this area have been initiated, for instance, in [1], [3], [18], [19], [21], [34].

In the late 1980s, the framework of nonlinear PDEs (partial differential equations) led to strong improvements in the formalization of regularization methods. First created to describe physical laws and natural motions of mechanic objects and fluids (strings, water, wind [52]), PDEs were already widely studied. Interesting results coming from the fields of physics and mathematics have been recently extended and used to improve data regularization schemes. Nonlinear PDEs succeed in smoothing data while preserving large global features such as contours and corners (discontinuities of the signal) and their use within variational frameworks has opened new ways to handle classical image processing issues (restoration, segmentation, registration, etc.). Thus, many PDE-based schemes have been presented so far in the literature, particularly for the regularization of 2D scalar images $I : \Omega \subset \mathbb{R}^2 \rightarrow \mathbb{R}$ (see, for instance, [2], [4], [27], [30], [34], [37], [51], [53], [54] and references therein).

Another interesting property of nonlinear regularization PDEs such as $\frac{\partial I}{\partial t} = \mathcal{R}$ is the notion of scale-space behind: The data are gently regularized step-by-step and a continuous sequence of smoother images $I(t)$ is generated whereas the evolution time $t$ goes by. Obviously, such regularization algorithms must let the less significant data features disappear first, while the interesting ones are preserved as long as they become unimportant themselves within the image. Roughly speaking, regularization PDEs may be seen as nonlinear filters that simplify the image little by little and minimize then the image variations. Note, therefore, that they generally do not converge toward a very interesting solution. Most of the time, the image obtained at convergence ($t \rightarrow \infty$) is constant, corresponding to an image without any variations: This is actually the most simplified image we can obtain. To avoid this effect, denoising algorithms are usually based on a regularization term $\mathcal{R}$ coupled with a data attachment term $(I_{\text{noisy}} - I)$, also called fidelity term. It avoids the expected solution (regularized image) at convergence to be too different from the original noisy image (not...
Fig. 1. Example of image restoration with surface area (functional) minimization. (a) Noisy image. (b) Corresponding surface. (c) Restored image. (d) Corresponding surface.

constant, by the way). Another classical restoration technique is done by stopping the pure regularization flow \( \frac{\partial I}{\partial t} = R \) after a finite number of iterations. In this article, we are mainly interested in the regularization term behavior rather than the fidelity term. For an interesting mathematical study about fidelity terms, please refer to [29], [31].

Extensions of these nonlinear regularization PDEs to vector-valued images \( I : \Omega \to \mathbb{R}^n \) have been recently proposed, leading to more elaborated expressions: A coupling between image channels generally appears in the equations, through the consideration of a local vector geometry, given pointwise by the spectral elements \( \lambda_+, \lambda_- \) (positive eigenvalues) and \( \theta_+, \theta_- \) (orthogonal eigenvectors) of the \( 2 \times 2 \) symmetric and semi-positive-definite matrix, also called structure tensor \([45],[48],[51],[55]\):

\[
G = \sum_{j=1}^{n} \nabla I_j \nabla I_j^T.
\]

Each \( \nabla I_j \) corresponds to the spatial gradient of the \( j \)th channel (i.e., vector component) of the vector-valued image \( I \). As demonstrated in \([55]\), the structure tensor \( G \) is particularly interesting since the eigenvalues \( \lambda_+, \lambda_- \) respectively, define the local min/max vector-valued variations of \( I \) in corresponding spatial directions \( \theta_+ \) (eigenvectors), i.e., the spectral elements of \( G \) define the local geometry of the vector-valued image discontinuities. (Note that \( \lambda_+ = \| \nabla I \| \) and \( \theta_+ = \nabla I / \| \nabla I \| \) for scalar images, when \( n = 1 \).

Starting from this basis, we can classify diffusion PDE’s schemes proposed in the literature into one of these three following approaches, related to different interpretation levels of the regularization process, described in Sections 1.1, 1.2, and 1.3 below.

1.1 Functional Minimization

Regularizing an image \( I \) may be seen as the minimization of a functional \( E(I) \) measuring a global image variation. The idea is that minimizing this functional will flatten the image variations, then gradually remove the noise:

\[
\min_{I : \Omega \to \mathbb{R}^n} E(I) = \int_{\Omega} \phi(N(I)) \, d\Omega,
\]

where \( N(I) \) is a norm related to local image variations and \( \phi : \mathbb{R} \to \mathbb{R} \) is an increasing function. One often chooses \( N(I) = \sqrt{\lambda_+} + \sqrt{\lambda_-} \) for vector-valued images \([7],[10],[33],[41],[46],[47]\), but other norms are possible such as \( N(I) = \sqrt{\lambda_+} \) \([9],[35],[36]\), or \( N(I) = \sqrt{\lambda_+} - \sqrt{\lambda_-} \) \([38],[49],[50]\). For scalar images \( I : \Omega \to \mathbb{R} \), these norms naturally reduce to the same expression \( N(I) = \| \nabla I \| \). Then, the minimization of \( (1) \) is performed through a gradient descent (PDE), coming from the Euler-Lagrange equations of \( E(I) \).

This technique has been widely used in the context of scalar images \([4],[15],[16],[24],[25],[54]\), for instance, by minimizing the area of a surface representing the image (Fig. 1). Corresponding references for vector-valued images are: \([10],[22],[33],[37],[39],[42],[44]\).

1.2 Divergence Expressions

A regularization process may be also more locally designed, as a diffusion of pixel values, viewed as chemical concentrations or temperatures \([51],[20]\), and directed by a \( 2 \times 2 \) diffusion tensor \( D \) (symmetric and definite-positive matrix):

\[
\frac{\partial I_i}{\partial t} = \text{div} \left( D \nabla I_i \right) \quad (i = 1..n).
\]

It is generally assumed that the spectral elements of \( D \) give the two weights and directions of the local smoothing performed by \( (2) \). \( D \) is then specially designed from the spectral elements of the structure tensor \( G \) in order to anisotropically smooth \( I \), while taking its intrinsic local geometry into account, preserving its global discontinuities. Anyway, we will show throughout this paper that the interpretation of the PDE \( (2) \) in terms of local smoothing is not so obvious. Actually, the spectral shape of the tensors \( D \) is not always representative of the effective smoothing performed by \( (2) \). This can be easily understood as follows: Let us consider a simple case of two different “divergence” tensors \( D_1 \) and \( D_2 \) defined by

\[
D_1 = \frac{\text{Id}}{\| \nabla I \|} \quad \text{and} \quad D_2 = \frac{1}{\| \nabla I \|^2} (\nabla I \nabla I^T).
\]

\( D_1 \) is isotropic (since it is only a weighted identity matrix) while \( D_2 \) is purely anisotropic (only one eigenvalue is nonzero). Nevertheless, it is easy to verify that

\[
\text{div} \left( D_1 \nabla I \right) = \text{div}(D_2 \nabla I) = \text{div} \left( \frac{\nabla I}{\| \nabla I \|} \right),
\]

which actually corresponds to the well-known TV minimization of scalar images: Two tensors with very different shapes lead to the same equation, accordingly to the same regularization behavior.
regularization approach, respecting desired local smoothing properties (Section 4), as well as propose new and adapted numerical schemes (Section 6). Finally, we apply our method to solve a wide range of image processing issues, including color image restoration, inpainting, magnification, and flow visualization (Section 7).

2 FROM VARIATIONAL TO DIVERGENCE FORMS

We first consider vector-valued image regularization as a variational problem. We want to find the corresponding divergence-based expression, i.e., the link (A) ⇒ (B).

2.1 A Generic Functional

Instead of regularizing a functional such as (1) depending on a predefined variation norm \( \mathcal{N}(I) \), we would rather propose to minimize this more generic \( \psi \)-functional:

\[
\min_{I: \mathbb{R}^n} E(I) = \int_{\Omega} \psi(\lambda_+, \lambda_-) \, d\Omega. \tag{5}
\]

As vector-valued images possess two distinct variation estimators \( \lambda_+ \) and \( \lambda_- \) (eigenvalues of the structure tensor \( \mathbf{G} = \sum_{j=1}^{n} \nabla I_j \nabla I_j^T \), it seems natural to minimize a functional defined by a function \( \psi : \mathbb{R}^2 \to \mathbb{R} \) of two variables instead of a single one. This is actually a generic extension of the \( \phi \)-function formulation for vector-valued images (4).

2.2 Corresponding Euler-Lagrange Equations

The Euler-Lagrange equations of (5) can be derived and reduced to a simple form of divergence-based expression (see Appendix A which can be found on the Computer Society Digital Library at http://computer.org/tkde/archives.htm for details about this Euler-Lagrange derivation):

\[
\frac{\partial I_i}{\partial I} = \text{div} (\mathbf{D} \nabla I_i) \quad (i = 1..n), \tag{6}
\]

where the \( 2 \times 2 \) diffusion tensor \( \mathbf{D} \) is defined as:

\[
\mathbf{D} = \frac{\partial \psi}{\partial \lambda_+} \theta_+ \theta_+^T + \frac{\partial \psi}{\partial \lambda_-} \theta_- \theta_-^T.
\]

It results then in a divergence-based equation such as (2), where the diffusion tensor \( \mathbf{D} \) is simply defined from the partial derivatives of \( \psi \), and the eigenvectors \( \theta_+ \), \( \theta_- \) of \( \mathbf{G} \). Note that the tensor \( \mathbf{D} \) has the same orientation as the structure tensor \( \mathbf{G} \) (same eigenvectors).

2.3 Link with Other Approaches

The choice of particular cases of \( \psi \)-functions leads to previous vector-valued regularization approaches defined as variational methods, such as the whole range of vector-valued \( \phi \)-functionals [33], [42]:

\[
\psi(\lambda_+, \lambda_-) = \phi(\sqrt{\lambda_+ + \lambda_-})
\]

or the Beltrami flow framework [22]:

\[
\psi(\lambda_+, \lambda_-) = \sqrt{(1 + \lambda_+)(1 + \lambda_-)}.
\]

More generally, our variational approach (5) shows that the eigenvalues of a divergence tensor \( \mathbf{D} \) can be seen as the gradient of a potential function \( \psi \), linked to the functional (5).
As we consider the oriented Laplacian-based equation (3).

3.1 Geometric Meaning of Oriented Laplacians

Let us consider the oriented Laplacian-based equation (3). As \( \xi \perp \eta \), this PDE can be equivalently written as:

\[
\frac{\partial I_i}{\partial t} = c_1 I_{i\xi} + c_2 I_{i\eta} = \text{trace} (T H_i) \quad (i = 1..n),
\]

(7)

where \( H_i \) is the Hessian matrix of the vector component \( I_i \) and \( T \) is the \( 2 \times 2 \) tensor defined by: \( T = c_1 \xi \xi^T + c_2 \eta \eta^T \), characterized by its two eigenvalues \( c_1, c_2 \) and its two corresponding eigenvectors \( \xi, \eta \). Let us suppose first that \( T \) is a constant tensor over the definition domain \( \Omega \).

Then, the formal solution of the PDE (7) is:

\[
I_{i\xi} = I_{i\xi(0)} * G^{(T,i)} \quad (i = 1..n),
\]

(8)

where \( * \) stands for the convolution operator and \( G^{(T,i)} \) is an oriented Gaussian kernel, defined by:

\[
G^{(T,i)}(x) = \frac{1}{4\pi t} \exp \left( -\frac{x^T T^{-1} x}{4t} \right) \quad \text{with} \quad x = (x \ y)^T.
\]

(9)

Proof. From the expression (9), we can compute the temporal and spatial derivatives of \( G^{(T,i)} \):

\[
\frac{\partial G^{(T,i)}}{\partial t} = -\frac{1}{4\pi t^2} \exp \left( -\frac{x^T T^{-1} x}{4t} \right) \left( 1 - \frac{x^T T^{-1} x}{4t} \right)
\]

and

\[
\begin{align*}
\nabla G^{(T,i)} &= -\frac{1}{8\pi t^2} \exp \left( -\frac{x^T T^{-1} x}{4t} \right) T^{-1} x \\
H_{G^{(T,i)}} &= -\frac{1}{8\pi t^2} \exp \left( -\frac{x^T T^{-1} x}{4t} \right) T^{-1} (\text{Id} - xx^T T^{-1}),
\end{align*}
\]

where \( \nabla G^{(T,i)} \) and \( H_{G^{(T,i)}} \) are, respectively, the gradient and the Hessian of \( G^{(T,i)} \).

It means that

\[
\text{trace}(T H_{G^{(T,i)}}) = -\frac{1}{8\pi t^2} \exp \left( -\frac{x^T T^{-1} x}{4t} \right) \text{trace} \left( \text{Id} - \frac{xx^T T^{-1}}{2t} \right)
\]

\[
= -\frac{1}{8\pi t^2} \exp \left( -\frac{x^T T^{-1} x}{4t} \right) \left( 2 - \frac{x^T T^{-1} x}{2t} \right)
\]

\[
= \frac{\partial G^{(T,i)}}{\partial t}.
\]

And, as the convolution is a linear operation, we have

\[
\frac{\partial (I_{i\xi} * G^{(T,i)})}{\partial t} = I_{i\xi} * \frac{\partial G^{(T,i)}}{\partial t}
\]

\[
= I_{i\xi} * \text{trace}(T H_{G^{(T,i)}})
\]

\[
= \text{trace}(T H_{I_{i\xi} * G^{(T,i)}})
\]

as well as

\[
\lim_{t \to 0} (I_{i\xi} * G^{(T,i)}) = I_{i\xi}
\]

which tells us that the initial condition at \( t = 0 \) is coherent both for the PDE and the convolution process, since the Gaussian function \( G^{(T,i)} \) is normalized.

It is a generalization of the Koenderinck’s idea [23], who proved this property in the field of computer vision for the isotropic diffusion tensor \( T = \text{Id} \), resulting in the well-known heat flow equation: \( \frac{\partial I}{\partial t} = \Delta I \).

Fig. 3 illustrates two Gaussian kernels \( G^{(T,i)}(x, y) \), respectively, obtained with isotropic and anisotropic tensors \( T \) (up) and the corresponding evolutions of the diffusion PDE (7) on a color image (down). It is worth to notice that the Gaussian kernels \( G^{(T,i)} \) give the classical

\[
\text{Fig. 3. Trace-based PDEs (7) viewed as convolutions by oriented 2D Gaussians.}
\]
representations of the tensors $T$ with ellipsoids. Conversely, it is clear that the tensors $T$ represent the exact geometry of the smoothing performed by the PDE (7).

When $T$ is not constant (which is generally the case), i.e., represents a field $\Omega \rightarrow \mathbb{R}^{2}$ of variable diffusion tensors, the PDE (7) becomes nonlinear and can be viewed as the application of temporally and spatially varying local masks $G_{i,j}(x)$ over the image $I$. Fig. 4 illustrates two examples of spatially varying tensor fields $T$, represented with fields of ellipsoids (up), and the corresponding evolutions of (7) on a color image (down). As before, the shape of each tensor $T$ gives the exact geometry of the local smoothing process performed by the trace-based PDE (7) point by point.

Note that this local filtering concept makes the link between a generic form of vector-valued diffusion PDEs expressed through a trace operator (7) and the Bilateral filtering techniques, as described in [5], [43]. Another similar approach based on non-Gaussian convolution kernels has been also proposed for the specific case of Beltrami Flow in [40].

With the PDE (7), we are naturally disassembling the regularization itself and its underlying smoothing geometry, which is given by the spectral elements of a trace-tensor $T$. Conversely to divergence equations, the choice of the tensor is unique here: The shape of the trace tensor $T$ is really giving the correct smoothing geometry performed by the PDE (7).

### 3.2 Trace-Based and Divergence-Based Tensors

Differences between divergence tensors $D$ in (2) and trace tensors $T$ in (7) can be understood as follows: We can develop the divergence equation (2) as:

$$\text{div} (\text{D} \nabla I_i) = \text{trace} (\text{DH}_i) + \nabla I_i^T \text{div} (\text{D}),$$

where $\text{div} ()$ is defined as a divergence operator acting on matrices and returning vectors:

$$\text{if } D = (d_{ij}), \text{div} (D) = \left( \begin{array}{c} \text{div}(d_{11}) \\ \text{div}(d_{12})^T \\ \text{div}(d_{21}) \\ \text{div}(d_{22})^T \end{array} \right).$$

Then, an additional term $\nabla I_i^T \text{div} (D)$ appears, connected to the spatial variation of the tensor field $D$. It may perturb the smoothing behavior given by the first part $\text{trace} (\text{DH}_i)$, which actually corresponds to a local smoothing directed by the spectral elements of $D$. As a result, the divergence-based equation (2) may smooth the image $I$ with weights and directions that are different than the spectral elements of $D$. This is actually the case for the scalar $\phi$-function formulation (4), where the smoothing process does not behave finally and, fortunately, as an isotropic one, despite the isotropic form of the divergence tensor $D = \frac{\phi'(|\nabla I|)}{||\nabla I||} \text{Id}$.

### 3.3 Developing the Divergence Form

Actually, if we consider that the divergence tensor $D$ only depends on the spectral elements of the structure tensor $G$:

$$D = f_1(\lambda_+, \lambda_-)\theta_+\theta_+^T + f_2(\lambda_+, \lambda_-)\theta_-\theta_-^T \quad (10)$$

with $f_1, f_2 : \mathbb{R} \rightarrow \mathbb{R}$, (which is the case for most of the proposed equations in the literature), then we can develop the corresponding divergence equation $\text{div} (\text{D} \nabla I_i)$ into oriented Laplacians, i.e., this trace-based PDE (full demonstration can be found in Appendix B which can be found on the Computer Society Digital Library at http://computer.org/tkde/archives.htm):

$$\text{div} (\text{D} \nabla I_i) = \sum_{j=1}^{n} \text{trace} ((\delta_{ij} D + \mathbf{Q}^{ij}) H_j), \quad (11)$$

where the $\mathbf{Q}^{ij}$ designates a family of $n^2$ matrices $(i,j = 1...n)$, defined as the symmetric parts of the following matrices $P^{ij}$ (then, $Q^{ij} = (P^{ij} + P^{ji})/2$):

$$P^{ij} = \alpha \nabla I_i^T \nabla I_j \text{Id}$$

$$+ 2\left( \frac{\partial \alpha}{\partial \lambda_+} \theta_+\theta_+^T + \frac{\partial \alpha}{\partial \lambda_-} \theta_-\theta_-^T \right) \nabla I_j \nabla I_i^T G$$

$$+ 2\left( \alpha + \frac{\partial \beta}{\partial \lambda_+} \theta_+\theta_+^T + \alpha + \frac{\partial \beta}{\partial \lambda_-} \theta_-\theta_-^T \right) \nabla I_j \nabla I_i^T.$$

Fig. 4. Trace-based PDEs (7) with nonconstant diffusion tensor fields $T$. Interpretation in terms of nonlocal filtering.
\[ \frac{\partial I_i}{\partial t} = \sum_{j=1}^{n} \text{trace} (A^{ij}H_i) \quad (i = 1..n), \]  

(12)

where the \( A^{ij} \) forms a family of \( 2 \times 2 \) symmetric matrices, and the \( H_i \) designate the Hessian matrices of \( I_i \). Actually, this expression can be equivalently written with a slight abuse of notations, in a super-matrix form:

\[ \frac{\partial I}{\partial t} = \text{trace} (A H), \]

(13)

where \( A \) is the matrix of diffusion tensors \( A^{ij} \) (and is itself symmetric), and \( H \) is the vector of Hessian matrices \( H_i \). The matrix product \( A H \) in (13) is then seen submatrix by submatrix, and the operator \( \text{trace}() \) returns the vector in \( \mathbb{R}^{n} \), corresponding to the trace of each submatrix in the resulting vector of matrices.

### 4.1 Link with Previous Expressions

The PDE (12) is a unifying equation that can be used to describe a wide range of vector-valued regularization:

- First, it develops both variational and divergence-based approaches (that can be written as

\[ \frac{\partial I_i}{\partial t} = \text{div} (D \nabla I_i), \]

as developed in Section 2) into a very local formulation. This particularly includes the works done in [10], [20], [22], [33], [37], [39], [42], [48], [51] among others. As described above, the \( 2 \times 2 \) tensors \( A^{ij} \) are then defined to be \( A^{ij} = \delta_{ij} D + Q^{ij} \). Note that the \( Q^{ij} \) \( (i \neq j) \) corresponds here to diffusion contributions of other channels \( I_j \) in the current one \( I_i \). This kind of diffusion energy transfer can be considered as a particular coupling of the corresponding vector-valued diffusion PDE.

- Second, the PDE (12) also gathers the oriented-Laplacian formulations \( \frac{\partial I_i}{\partial t} = \text{trace} (TH_i) \), by choos-
5 A NEW REGULARIZATION PDE

We propose now to design a new vector-valued regularization PDE that follows desired local geometric properties (particularly for image denoising). These constraints will naturally define a specific form of regularization PDE, from the very generic form (12):

- We do not want to mix diffusion contributions between image channels. The desired coupling between vector components \( I_i \) should only appear in the diffusion PDE through the computation of the structure tensor \( \mathbf{G} \), in order to control the local smoothing behavior of the regularization process. This means we have to define only one diffusion tensor \( \mathbf{A} \), then choose \( A^{ij} = \delta_{ij} A \). Undesired coupling terms are then avoided.
- On homogeneous regions (corresponding to low vector variations), we want to perform an isotropic smoothing, i.e., a 2D heat flow that smoothes the noise efficiently with no-preferred directions: \( \frac{\partial I}{\partial t} \approx \Delta I = \text{trace}(\mathbf{H}_i) \). The tensor \( \mathbf{A} \) must then be isotropic in these regions:
  \[
  \lim_{(\lambda_+ + \lambda_-) \to 0} \mathbf{A} = \alpha \mathbf{I}
  \]

On vector edges (corresponding to high vector variations), we want to perform an anisotropic smoothing along the vector edges \( \theta \), in order to preserve them while removing the noise: \( \frac{\partial I}{\partial t} = \text{trace} (\beta \theta \theta^T \mathbf{H}_i) \), where \( \beta \) is a function decreasing anyway for very high variations, avoiding the oversmoothing of sharp corners. The tensor \( \mathbf{A} \) must be anisotropic in these regions:

\[
\lim_{(\lambda_+ + \lambda_-) \to \infty} \mathbf{A} = \beta \theta \theta^T.
\]

The following multivalued regularization PDE respects all these local geometric properties:

\[
\frac{\partial I_i}{\partial t} = \text{trace} (\mathbf{TH}_i) \quad (i = 1..n),
\]

where \( \mathbf{T} \) is the tensor field defined pointwise as:

\[
\mathbf{T} = f_-(\sqrt{\lambda^+_\sigma} + \lambda^-_\sigma) \theta^- \theta^-^T + f_+(\sqrt{\lambda^+_\sigma} + \lambda^-_\sigma) \theta^+ \theta^+^T.
\]

\( \lambda^\pm_\sigma \) and \( \theta^\pm_\sigma \) are defined to be the spectral elements of \( \mathbf{G}_\sigma = \mathbf{G} * \mathbf{G}_\sigma \), a Gaussian smoothed version of the structure tensor \( \mathbf{G} \), allowing us to retrieve a more coherent vector-geometry and giving a better approximation of the vector discontinuities directions (see also [51]). For our experiments in Section 7, we chose

\[
f_+(s) = \frac{1}{1 + s^2} \quad \text{and} \quad f_-(s) = \frac{1}{\sqrt{1 + s^2}}.
\]

This is, of course, one possible “empiric” choice (inspired from the hypersurface formulation of the scalar case [4]) that verifies the above geometric properties, relying on practical experience.

The point is that we can easily adapt the weighting functions \( f_+ \) and \( f_- \) to obtain regularization behaviors for specific problems, since we are sure of the local smoothing.

![Fig. 8. Using our vector-valued regularization PDE (14), for color image restoration. (a) Noisy color image and (b) restored color image.](image)

![Fig. 9. Using our vector-valued regularization PDE (14), for improvement of lossy compressed images. (a) Lossy compressed JPEG image and (b) Improved color image.](image)
process performed by (14). This vector-valued regularization equation smooths the image in coherent spatial directions and preserves then well the edges, by allowing only the necessary geometric coupling between vector channels $I_i$. Its form has steadily followed the local analysis of classical multivalued regularization algorithms.

6 Numerical Schemes

The numerical implementation of the PDE (14) can be done with classical numerical schemes, based on spatial discretizations with centered finite differences of the gradients and the Hessians [28]. Here, we propose an alternative approach based on the local filtering interpretation of trace-based equations (7), proposed in Section 3. The idea is as follows: The smoothing can be locally performed by applying a spatially varying mask over the image. For each point \((x, y)\) of the image \(I\), we compute the oriented Gaussian kernel \(G(T, \tau)\) corresponding to the tensor \(T\), defined by (14). Then, we apply it on each local neighborhood \(I_i(x, y)\), as shown in Fig. 5.

The main advantages of this numerical scheme are:

1. It numerically preserves the maximum principle since the local filtering is done only with normalized kernels.
2. It is more precise, since the computed local kernel corresponds exactly to the smoothing to perform. No (imprecise) second derivatives have to be computed (Fig. 6), and local filtering kernel is better oriented.

As for the shortcomings of this scheme, we have to mention that it is more time-consuming, since we have to compute a different Gaussian kernel (i.e., exponential functions) at each image point and for each iteration. For our experiments, we chose \(5 \times 5\) convolution kernels (Fig. 6). Note how edge details are better preserved in Fig. 6c (look at the glint inside the eye).

7 Applications

We illustrate here the wide range of image processing applications that we can handle with our presented approach, through our vector-valued regularization PDE (14).

7.1 Color Image Restoration

Despite the emergence of digital cameras, color image restoration may be still needed. Fig. 8 represents a digital photograph with real noise, due to the bad lighting conditions during the snapshot. Our vector-valued regularization PDE can successfully remove the noise, while preserving the global features of the image (see also Fig. 7).

7.2 Improvement of Lossy Compressed Images

Digital images, due to their big memory size, are often stored in a more compact form obtained with lossy compression algorithms (JPEG being the most popular). It often introduces visible image artefacts: For instance, block effects are classical JPEG drawbacks. Using our flow (14) significantly improves the quality of such degraded images (Fig. 9). In this case, we chose a high parameter \(\sigma\) (variance of the structure tensor presmoothing), since a lot of structures in this image are quite linear. It helps then to retrieve linear structure, such as the gnome’s hair.

7.3 Color Image Inpainting

Recently, an interesting application of diffusion PDEs named image inpainting, has been proposed in [8], [12], [13], [14]. It consists of filling undesired holes (defined by

the user) in an image by interpolating the data located at the neighborhood of the holes. It is possible to do that by applying our PDE (14) only in the holes to fill: boundaries pixels will be diffused until they completely fill the missing regions, in a structure-preserving way. Important issues may be solved with this kind of algorithms as, for instance: removing text on images (Fig. 10), removing real objects in photographs (Fig. 10) or reconstruct partially coded images for image compression purposes (Fig. 11).

7.4 Color Image Magnification
With the same techniques, one can easily perform image magnification. Starting from a linear interpolation of a small image, and applying our PDE (14) on the image (excepted on the original known pixels), we can retrieve nonlinear magnified images without jagging or bloc effects, inherent to classical linear interpolation techniques (Fig. 12).

7.5 Flow Visualization
Considering a 2D vector field \( F : \Omega \rightarrow \mathbb{R}^2 \), we have several ways to visualize it. We can first use vectorial graphics (Fig. 13a), but we have to subsample the field since this kind of representation is not adapted to represent big flows. A better solution is as follows: We smooth a completely noisy (color) image \( I \), with a regularizing flow equivalent to (14) but where \( T \) is directed by the directions of \( F \), instead of the local geometry of \( I \):

\[
\frac{\partial I}{\partial t} = \text{trace} \left( \frac{1}{\|F\|} F F^T \right) H_i \quad (i = 1..n) \tag{15}
\]

Whereas the PDE evolution time \( t \) goes by, more global structures of the flow \( F \) appear, i.e., a visualization scale-space of \( F \) is constructed (Fig. 14). Here, our used regularization equation (15) ensures that the smoothing of the pixels is done exactly in the direction of the flow \( F \). This is not the case in [6], [11], [17], where the authors based their equations on a divergence expression. Using similar divergence-based techniques would raise a risk of smoothing the image in false directions, as this has been pointed out in Section 3.

8 Conclusion and Perspectives
In this paper, we proposed a new formalism allowing to express a large set of previous vector-valued regularization approaches within a common local expression. This formulation is particularly adapted to understand the local smoothing behavior of diffusion PDEs. Indeed, it explains the link between the diffusion tensor shapes in divergence or trace-based equations, and the actual smoothing performed by these processes, in term of local filtering. From this general study, we defined a new and particular regularization equation, based on the respect of a coherent anisotropic smoothing preserving the global features of vector images. We proposed as well specific numerical schemes adapted for accurate implementations. The application to several problems related to color images and flow visualization illustrated the efficiency of our method to deal with concrete cases based on the use of vector-valued regularization processes.
